# 1 Introduction

This document describes the **PnET-Succession** extension for the LANDIS-II model. For information about the model and its core concepts including succession, see the *LANDIS-II Conceptual Model Description*.

The PnET-Succession extension is based on the Biomass Succession extension of Sheller and Mladenoff (2004), embedding elements of the PnET-II ecophysiology model of Aber et al (1995) to simulate growth as a competition for available light and water, replacing the existing competition for “growing space” algorithms.

## 1.1 Major modifications made to PnET algorithms

Several modifications were made to PnET algorithms to make them tractable at landscape scale, primarily by broadening the scale of integration operations. (1) The PnET timestep was broadened from daily to monthly. (2) The number of sub-layers within a canopy layer was 50 in Pnet, but is here dynamically determined with a minimum of 5, where each sub-layer represents an even proportion of the total LAI within the layer. It can increase dynamically when transpiration would otherwise exceed soil water. These smaller subcanopy layers tighten the feedback between photosynthesis and water stress. (3) Cohort biomass is used as a surrogate for tree height to simulate canopy layers, which are added when the variation in biomass among cohorts exceeds a user-defined amount. (4) Photosynthates are allocated to four pools (foliage, root, wood and non-structural carbon (reserves)). Net photosynthesis is initially allocated to the NSC pool, and then foliage allocation occurs, followed by allocation to root and wood pools such that the above- and below-ground biomass ratio is preserved. Maintenance respiration is then deducted from the NSC pool. Details of model structure and modifications can be found in De Bruijn et al (2014).

## 1.2 Advantages and disadvantages of PnET-Succession compared to Biomass Succession

The goal for PnET-Succession was to make the simulation of growth and competition more mechanistic and more explicitly linked to fundamental drivers that are changing, such as climate and

atmospheric composition (e.g., CO<sub>2</sub> and ozone). It is believed that this more mechanistic approach will be more robust for making projections under climate and other global changes (Gustafson 2103).

### *Advantages of PnET-Succession compared to Biomass Succession*

- 1) PnET-Succession replaces the input parameters ANPP<sub>max</sub> and B<sub>max</sub> of LANDIS-II Biomass Succession with mechanistic calculations of growth and senescence that depend on climatic conditions and competition for resources. Establishment and growth are now emergent properties of the model and are explicitly linked to changing fundamental drivers such as climate and CO<sub>2</sub> concentrations.
- 2) Dynamic calculations of LAI and photosynthesis allow cohorts to die prior to senescence, based on physiological constraints (too few carbon reserves). This can typically occur when carbon reserves production is insufficient to support growth due to shading, water competition, drought, diseases or pests. This allows more realistic simulation of cohort death in the course of stand development (i.e., mortality is highest in the younger cohorts), and a more realistic accounting of biomass accumulation. An added benefit is that the number of cohorts to be simulated is reduced.
- 3) PnET-Succession allows a more explicit simulation of species' survival strategies, by implementing a dynamic competition for light and water. For example, one can parameterize species or species-group combinations of respiration losses and water use efficiency to implement competition advantages or disadvantages for particular species in sites that are dry or shaded due to competing vegetation.

### *Disadvantages of PnET-Succession compared to Biomass Succession*

- 1) PnET-Succession requires more parameters, which adds to uncertainty and increases the parameter burden when using the model. However, uncertainty may be no higher than when making *ad hoc* assumptions for other succession extensions about how novel conditions will affect modeled processes.
- 2) Runtimes tend to be somewhat longer, but only slightly longer because many cohorts senesce prior to reaching longevity age, greatly reducing the number of cohorts that must be simulated. In both BiomassSuccession and PnET-Succession, simulation of dispersal is more time consuming than the forest growth part.

## 1.4 Acknowledgments

Funding for the development of the PnET-Succession extension was provided by a grant from the USDA/NASA NIFA/AFRI program to Purdue University. Valuable scientific contributions to the development of the extension were made by Arjan De Bruijn, Eric J. Gustafson, Brian R. Sturtevant and Mark Kubiske.

Funding for the development of LANDIS-II was provided by the Northern Research Station (Rhinelander, Wisconsin) of the U.S. Forest Service. Valuable contributions to the development of LANDIS-II were made by Robert M. Scheller, Brian R. Sturtevant, Eric J. Gustafson, and David J. Mladenoff.

## 2 PnET-Succession

The PnET-Succession Extension generally follows the methods of the Biomass Succession Extension: Age cohorts reproduce, grow (add biomass), age, and die. The PnET-Succession Extension replaces the simple growth and competition algorithms from the Biomass Succession Extension with the photosynthesis and respiration equations from PnET-II to simulate growth of specific cohort biomass components (root, foliage, wood, non-structural carbon) as a competition for water and light.

PnET-Succession simulates the competition of cohorts for water and light as a function of photosynthetic processes. Competition for water is simulated on each site (grid cell) through a dynamic soil water balance that receives precipitation and loses water as runoff, interception, percolation out of the rooting zone and consumption by cohorts through photosynthesis, respiration and transpiration. Competition for light is modeled by tracking solar radiation through canopy layers (related to cohort age) according to a standard Lambert-Beer formula. PnET-Succession requires average monthly temperature, precipitation, photosynthetically active radiation and atmospheric CO<sub>2</sub> concentration as inputs.

Because monthly climate data are provided as an input to the extension, species establishment probability is also calculated at each time step as a function of the climate conditions during the time step.

The PnET-Succession Extension also changes the calculation of shade. LAI is estimated for multiple canopy layers, and available light is computed for each layer, including the sub-canopy (i.e., ground).

The PnET-Succession Extension tracks biomass in four live pools (foliage, roots, wood and non-structural (C reserves)) and two dead pools (woody and leaf litter).

### 2.1 Initializing Biomass

At the beginning of a scenario, the initial communities begin with appropriate living and dead biomass values estimated for each site.

**However, the user does not supply the initial biomass estimates.**

Rather, the PnET-Succession extension uses its growth algorithms to iterate the number of time steps equal to the maximum cohort age for each site. Beginning at time (t - oldest cohort age), cohorts are added at each time step corresponding to the time when the existing cohorts

were established. Thus, each cohort undergoes growth and mortality for the number of years equal to its current age, and its initial biomass value reflects competition among cohorts. Note: this is a computationally intensive process that may require significant time for complex initial landscapes. Additionally, climate data are required back to  $t$  - oldest cohort age. To facilitate climatic input in years where weather records do not exist, it is possible to supply mean monthly climate data for a range of years (see section 6.2)

This biomass initialization does not account for disturbances that would likely happen prior to initialization and therefore tends to overestimate initial live biomass and underestimate initial dead biomass.

## 2.2 LAI Shade Calculation

Site shade is calculated based on LAI in canopy layers (see section 2.5).

## 2.3 Cohort Reproduction and Establishment

Cohort establishment is the result of two distinct processes. 1) production and dispersal of seeds and 2) seed germination and successful recruitment of a viable new cohort.

Seed is produced by every cohort that is at least the age of sexual maturity. Seed dispersal is modeled as a spatial process according to the dispersal method selected by the user, as in the Biomass Succession extension.

When seeds disperse to a cell, establishment (recruitment) first requires sufficient light (amount dependent on species shade tolerance) and is then stochastic based on a probability of establishment that is calculated as a function of soil moisture and sub-canopy radiation during the time step. Establishment is only attempted during optimal months, computed from the climate file as the first three physiologically active months in the year and one month after the maximum precipitation. Initial biomass is computed for a 1-year old cohort.

Note: this initial cohort will be grouped ('binned') appropriately into a larger cohort (e.g., age 1 – 10) at the next succession time step.

## 2.4 Cohort Competition

Biomass growth is driven by photosynthesis, which depends on light, soil moisture and foliage biomass. Multiplicative reduction factors are applied to gross photosynthesis to account for water stress, suboptimal radiation, vapor pressure deficit, and temperature.

### 2.4.1 Light

The reduction of radiation intensity through the canopy is estimated using an exponential decrease function (i.e., Beer-Lambert law), where incoming radiation drives photosynthetic activity (Aber and Federer, 1992). A laboratory-derived relationship between foliar nitrogen concentration and assimilation rates under optimal growth conditions is used to estimate potential gross photosynthesis.

PnET-Succession assumes that LAI and biomass are spatially homogeneous on a site (i.e., cell). PnET-Succession defines canopy layers according to biomass, with high biomass cohorts achieving dominance with regard to access to light. Because senescing trees are more likely to lose biomass due to branches breaking off than due to the top breaking (i.e. they lose biomass without losing height), maximum lifetime biomass of a tree-species cohort is used as a proxy for tree height. Note that changes have been made to the model described paper in Ecological Modeling (De Bruijn et al 2014). We no longer set (arbitrary) age limits on the development of canopy layers. Rather, each cohort is divided into a number IMAX (=5 by default, set in the GenericParameters file) of canopy sublayers of equal biomass (Figure 1, left). The cohort sublayers are overlaid and the model iteratively clusters sublayers into canopy layers until the deviation of the newly formed canopy boundaries (i.e. LyrMax - LyrAv) decreases below a user defined parameter MaxDevLyrAv (Figure 1, right). This process produces boundaries of canopy layers such that the variation of subcanopy boundaries within the canopy layers is minimized and the variance of subcanopy boundary between canopy layers is maximized. MaxDevLyrAv is calibrated by the user to produce the maximum number of canopy layers expected in the system. Subcanopy layers within a canopy layer have equal access to the light reaching the canopy layer, and the light passing through a canopy layer is a function of the LAI and extinction coefficient of the cohorts making up the canopy layer. Light stress for a cohort is calculated by:  $fRad = Radiation / (Radiation + HalfSat)$ .

Figure 1. Canopy layer computation. Each tree represents a species-cohort, and the solid horizontal lines are subcanopy boundaries. Dotted lines are computed canopy layer boundaries that determine the assignment of subcanopy layers to canopy layers.

### 2.4.2 Water

Soil water is calculated in a bulk-hydrology model that updates soil water depending on precipitation and consumption by the trees. Sources of bulk soil water (*soil\_water* in mm) are precipitation (*P* in mm/month) and melting water (*snow\_melt* in mm/mo). Precipitation is allocated either directly to *soil\_water* or to snow (*snow\_pack* in mm) where it remains until air temperature induces melting. Sinks of *soil\_water* are PrecipitationLoss (runoff, evaporation), Leakage (percolation) and Transpiration (Figure 2.). Losses due to runoff and evaporation are controlled by a user-defined ecoregion parameter (PrecipLossFrac) which is intended to increase with slope or other factors that would increase runoff and/or surface evaporation. Water that infiltrates the soil is subject to both fast and slow Leakage.

Infiltration is limited by the soil saturation ( $\theta_s$ ), and any water in excess of saturation is subject to runoff. Fast leakage is correlated to the soil hydraulic conductivity ( $K_{sat}$ ) and occurs before plants have a chance to utilize water. Slow leakage occurs after plant use (transpiration) and keeps the water level at or below field capacity (-3.37 m pressure head) at the end of each monthly time step.

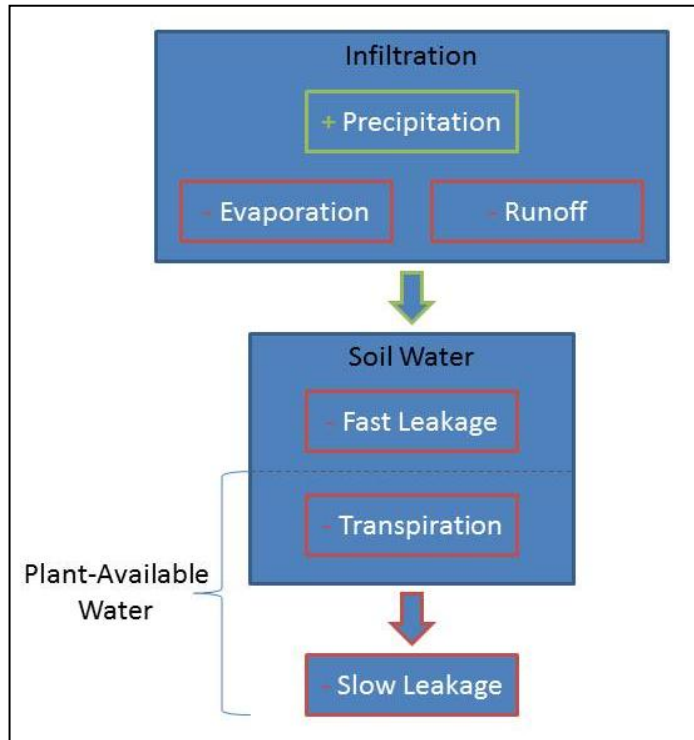

Figure 2. Soil water processes in PnET-Succession

Water stress in the model depends on the water pressure in the soil according to Feddes et al. (1978). Water pressure in the soil (PF curves) depends on soil water content and the soil type according to Arah and Vinten (1995), who produced PF curves for common soil types through an approximation using four parameters ( $\theta_R$ ,  $\theta_S$ ,  $\alpha$ ,  $n$ ). Pressure head ( $h$ ) is related to soil water content ( $\theta$ ) according to van Genuchten (1980; Eq. 21):

$$\theta = \theta_R + \frac{(\theta_S - \theta_R)}{[1 + (\alpha h)^n]^{1-\frac{1}{n}}}$$

Default values for the required parameters (from Leij et al. 1996) are provided with PnET-Succession for 12 different soil types (Figure 3, left panel), but users are able to modify existing soil type parameters or provide custom soil types with parameters. The user implements a soil type as an ecoregion-specific parameter in the ecoregion parameter table using a corresponding abbreviation for the soil type.

Water stress for a species-cohort is calculated from soil water pressure using four species-specific water pressure thresholds (Figure 3, right panel) labeled H1-H4 in Feddes et al. (1978). Note that PnET-Succession uses the absolute value of pressure head. Parameter H1 (the pressure head below which photosynthesis cannot occur (waterlogging)) is hardcoded in PnET-Succession ( $H1 = 0$  meter pressure). Often, little is known about H2 (cessation of waterlogging stress), in which it is recommended to use the generic value  $H2=0.0$ . H3 (onset of stress caused by too little water) can be set to reflect the drought sensitivity of a species, and should fall somewhere between H2 and H4. Most literature sources use a generic H4 (cessation of photosynthesis because of inadequate water) of -153 m pressure head (wilting point).

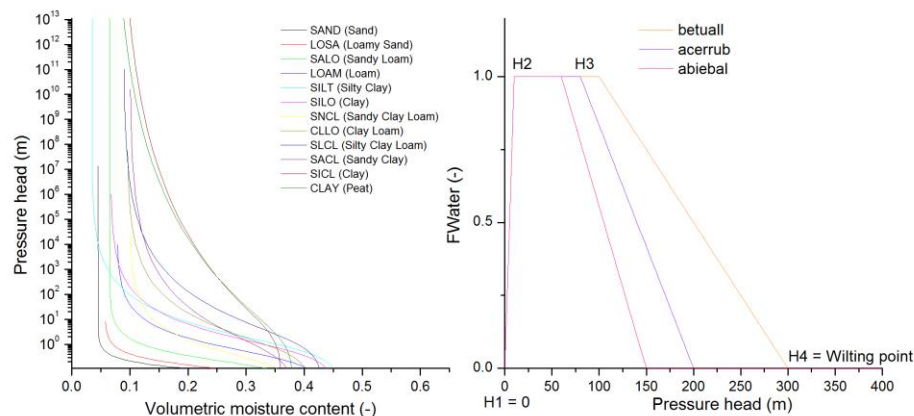

Figure 3. Pressure head (left) and inverse water stress (FWater, right). FWater is calculated by linear interpolation between parameters H0-H4. H0=0 is hardcoded and cannot be changed by the user.

### 2.4.3 Other factors

Vapor pressure deficit is calculated from the temperature fluctuations during the day, and accounts for the effect of supra-optimal

atmospheric CO<sub>2</sub>. Species-specific minimum and –optimum temperature are input as model parameters, and species specific maximum temperature is derived assuming a parabolic, symmetric optimum between species-specific maximum and minimum temperature for photosynthesis. The temperature reduction factor is calculated by: Foliar respiration is calculated as a user-defined fraction of maximum gross photosynthesis, modified by a temperature reduction factor using a Q-10 relationship.

## 2.5 Cohort Growth and Ageing

Net photosynthesis is estimated by subtracting respiration from gross photosynthesis. Resulting net photosynthesis is then allocated to maintenance respiration and then to the root, foliage, wood and non-structural biomass pools, according to fixed allocation ratios. A proportion of foliage and wood biomass is also moved to the dead pools to simulate leaf-fall and branch/root death. Cohort ageing is simply the addition of the time step to each existing cohort age.

## 2.6 Cohort Senescence and Mortality

Senescence is implemented as a reduction of gross photosynthetic rate with age such that respiration eventually exceeds production and cohorts die. A cohort dies when non-structural carbon decreases to <1% of the combined structural biomass pools. The PsnAgeRed parameter controls the shape of the function used to calculate the age-related reduction factor, which reaches zero at the longevity specified in the LANDIS-II species parameter file.

## 2.7 Dead Biomass Decay

When a cohort dies and is removed (e.g., fire or harvest), its biomass is added to one or both of the dead biomass pools: woody and leaf. Decomposition rate of woody litter depends on a decay rate that is weighted by additions of woody material and user-supplied species specific decay rates (KWdLit). Decomposition rate of non-woody litter depends on a weighted decay rate according to additions of foliage and their associated decomposition rates that depend on species specific foliage lignin concentrations (FolLignin) and ecosystem determined AET according to Meentemeyer (1978). Disturbances can alter the dead biomass pools. They can add dead biomass (e.g., wind) and/or remove dead biomass (e.g., fire may add some woody dead biomass and remove all leaf dead biomass).

### 3 Input File - PnET-Succession

The input parameters for this extension are specified in two input files: the PnET-Succession input file and the PnET Species Parameters input file. The general species parameter input file used by all versions of LANDIS is also required, and is described in Chapter 6 of the *LANDIS-II Model User Guide*. The input files must comply with the general format requirements described in section 3.1 *Text Input Files* in the *LANDIS-II Model User Guide*.

#### 3.1 Example PnET-Succession input file

```
LandisData  "PnET-Succession"

Timestep  10
StartYear 1961
SeedingAlgorithm  WardSeedDispersal
Latitude  45
MaxDevLyrAv      8000
IMAX            5

PNEToutputsites
PNEToutputSiteLocation 9 9
PNEToutputSiteLocation 12 15

InitialCommunities      Mid-succ-One_cell_initial-communities.txt
InitialCommunitiesMap   One_cell_initial-communities.img

PNETGenericParameters   PNETGenericParameters.txt

PNETSpeciesParameters   PNET_Oconto_species.txt

>> *****

EcoregionParameters     AssembX_4cell_EcoregionParameters.txt
```

#### 3.2 LandisData

This parameter's value must be "PnET-Succession"

#### 3.3 Timestep

This parameter is the time step of the extension. Value: integer > 0.  
Units: years.

#### 3.4 StartYear

This parameter indicates the climate year in which simulation begins. Climate file observations prior to this date are used for spin-up (as necessary) and observations from this date forward are used for

simulations. The climate file may contain more years than will actually be used by the model. Value: integer > 0. Units: years.

### 3.5 SeedingAlgorithm

This parameter is the seed dispersal algorithm to be used. Valid values are "WardSeedDispersal", "NoDispersal" or "UniversalDispersal". The algorithms are described in section 4.5.1 *Seeding of the LANDIS-II Conceptual Model Description*.

### 3.6 Latitude

The approximate latitude of the study area. Value:  $-90 < \text{integer} < 90$ . Units: degrees of latitude.

### 3.7 MaxDevLyrAv

This optional parameter is used to lump species-age cohorts into canopy layers, and specifies the maximum variation of cohort biomass that can occur within a canopy layer. It is given a default value of a maximum float, which results in a single canopy layer regardless of biomass distribution amongst subcanopy layers (See Section 2.4).

### 3.8 MaxCanopyLayers

Optional parameter that caps the number of canopy layers that can be implemented. Typically, forest canopy layers will not exceed 5 and applying many canopy layers delays the model dramatically. The number of canopy layers should primarily be regulated through MaxDevLyrAv, but when MaxDevLyrAv is given low values, the result would otherwise be an extreme number of canopy layers. MaxCanopyLayers has a default value of 5.

### 3.9 IMAX

Optional: Each cohort is subdivided in a number of layers (IMAX) for integration. In PnET (Aber and Federer, 1992), the number of subcanopy layers was fixed at 50. Reducing IMAX saves computation time, with robust results when  $\text{IMAX} > \sim 5$  (De Bruijn et al., 2014). When omitted, the model uses the default  $\text{IMAX}=5$ .

### 3.10 PNETOutputsites

Optional: Specify a site in the landscape to generate output files of monthly variable values for each cohort present on the site. There are

two options to specify a location. The keyword PNETOutputsites has to precede a list that contains at least one location.

1. If the input map has a projection, you can specify the map coordinates of your target output locations. First, specify the reference coordinates (upper left corner) of the map:

MapCoordinates        top, left

You can find the map coordinates in ArgGis by right-clicking: your map -> properties -> extent -> top, left

Second, provide a list with at least one coordinate:

PNEToutputSiteCoordinates X        Y

2. Alternatively, you can specify your target output locations according to their grid location (row, column) in the map:

PNEToutputSiteLocation row col

### 3.11 InitialCommunities

This parameter gives the name of the initial communities text file. This file assigns species and cohorts to each value found in the initial communities map (see chapter 4).

### 3.12 InitialCommunitiesMap

This parameter gives the file name of the initial communities map. This map contains a unique integer value for each combination of species and cohorts found on the landscape. Each cell value for an active site on the landscape must be one of the map codes listed in the initial communities input file

### 3.13 PnETGenericParameters

This optional parameter gives the name of a PnET Generic Parameter text file. Any parameter that is typically specified in the PnETSpeciesParameter file (Chapter 8), but is identical for all species can be supplied either in the default generic parameter file installed in C:\Programs\...\Extensions \ GenericPnETSpeciesParameters.txt with the rest of the model, or in a custom generic parameter file specified here. Any parameters not specified in the PnETSpeciesParameter file will be read from the custom generic file, and if not found there, will be read from the default generic file. Thus, values found in the PnETSpeciesParameter file will always take precedence over generic

files. The format of the PnET Generic Parameter text file is described in chapter 7.

### **3.14PnETSpeciesParameters**

This parameter gives the name of the PnET Species Parameter text file. The format of this file is described in chapter 8.

### **3.15EcoregionParameters**

This parameter gives the name of the PnET Ecoregions Parameter text file, which is described in chapter 9.

## 4 Input File – Initial community classes

This file contains the definitions of the initial community classes. Each active site on the landscape is assigned to an initial community class. The class specifies the tree species that are present along with the particular age cohorts that are present for each species.

### 4.1 Example File

```
LandisData "Initial Communities"

>>Old jackpine oak
MapCode 7
  acerrubr 30
  pinubank 80 90
  pinuresi 110 140
  querelli 40 120 240

>> young jackpine oak
MapCode 0
  pinubank 30 50
  querelli 10 40 70

>> young aspen
MapCode 2
  poputrem 10 20

>> old maple hardwoods
MapCode 55
  abiebals 10 60 120
  acerrubr 90 120
  acersacc 20 50 150 200
  betualle 40 140 200
  fraxamer 10 100 130 180
  piceglau 180
  querrubr 100 160 180
  thujocci 200 240 260
  tiliamer 20 80 110 150
  tsugcana 30 80 120 220 320 340

>> old pine - spruce - fir
MapCode 6
  abiebals 10 50 80
  piceglau 100 140 180 200 220
  pinuresi 140 160 180
  pinustro 200 280 350
```

## 4.2 LandisData

This parameter's value must be "Initial Communities".

## 4.3 Initial Community Class Definitions

Each class has an associated map code and a list of species present at sites in the class.

### 4.3.1 MapCode

This parameter is the code used for the class in the input map (see chapter 5). Value:  $0 \leq \text{integer} \leq 65,535$ . Each class map code must be unique.

Map codes can appear in any order, and need not be consecutive.

### 4.3.2 Species Present

A list of species present at the class' sites comes after the map code. Each species is listed on a separate data line.

```
species age age age ...
```

The species name comes first, followed by one or more ages. The name and ages are separated by whitespace. An age is an integer and must be between 1 and the species' Longevity parameter. The ages can appear in any order.

```
acersacc 10 5 21 60 100
```

The list may be empty, which will result in the sites in the class being initialized with no species cohorts.

### 4.3.3 Grouping Species Ages into Cohorts

The list of ages for each species is grouped into cohorts based on the succession extension's timestep. This timestep determines the size of each cohort. For example, if the timestep is 20, then the cohorts are ages 1 to 20, 21 to 40, 41 to 60, etc.

Suppose an initial community class has this species in its list:

```
acersacc 10 25 30 40 183 200
```

If the succession timestep is 10, then the cohorts for this species initially at each site in this class will be:

```
acersacc 10 20 30 40 190 200
```

## 5 Input File – Initial community map

This is a GIS file of the initial community classes. Each active site on the landscape is assigned to a MapCode that links to the initial community class defined in the Initial Community Class Definitions.

## 6 Input File – Climate

This file contains weather records of monthly parameter values.

### 6.1.1 Example File #1

Year	Month	TMax	TMin	PAR	Prec	CO2
2007	1	11.86	-13.39	564.2	1.651	383
2007	2	17.93	-8.45	698.7	1.7272	383

2008	10	26.3	-2.018	775.7	6.0198	385
2008	11	21.96	-7.66	671.0	0.4064	385
2008	12	20.11	-10.58	532.8	14.224	387

## 6.2 Header Information

The first line of the file must contain the following text:

Year	Month	TMax	TMin	PAR	Prec	CO2
------	-------	------	------	-----	------	-----

## 6.3 Observations

Subsequent lines of the file contain monthly values for the 7 variables. Observations must appear in chronological order.

### 6.3.1 Year

The year of the weather observation. Alternatively, a range of years may appear, delineated by a hyphen (see example 6.1.2). Value: 4-digit integer >0.

### 6.3.2 Month

The month of the weather observation. Value:  $1 \leq \text{integer} \leq 12$ .

### 6.3.3 TMax

The maximum temperature observed in the month. Value: decimal.  
Units: degrees C.

### 6.3.4 TMin

The minimum temperature observed in the month. Value: decimal.  
Units: degrees C.

### 6.3.5 PAR

Mean monthly value of Photosynthetically Active Radiation during daylight hours. Value: decimal  $\geq 0.0$ . Units: User choice. Typically  $\mu\text{mol}/\text{m}^2/\text{sec}$  or  $\text{W}/\text{m}^2$ . The units for the half-saturation constant (SpeciesParameter file) must be the same as PAR. **THE MODEL WILL NOT CHECK TO ENSURE THAT THE UNITS ARE THE SAME.** This is a user responsibility.

### 6.3.6 Prec

The sum of precipitation observed in the month. Value: decimal  $\geq 0$ .  
Units: mm.

### 6.3.7 CO2

Atmospheric CO<sub>2</sub> concentration. Value: decimal  $> 0$ . Units: ppm.

## 7 Input File – Generic PnET Species Parameters

This file contains PnET species parameters that are identical for all species. Only parameters that are not described in Chapter 8 are described here. Parameters may appear in any order.

### 7.1 Example file:

```
PnETGenericParameters
DVPD1                0.05
DVPD2                2
BFolResp             0.1
TOroot               0.02
TOWood               0.01
Q10                  2
FolLignin            0.2
KWdLit               0.01
InitialNSC            7
MaxSlwFrac           0.5
CFracBiomass          0.45
PreventEstablishment true
FolAddResp            1
H2                   0.0
H4                   150
```

### 7.2 PnETGenericParameters

This parameter's value must be "PnETGenericParameters".

### 7.3 DVPD1, DVPD2

Coefficients for converting vapor pressure deficit (VPD) to DVPD according to  $DVPD = 1 - DVPD1 * vpd^{DVPD2}$  (photosynthesis reduction factor due to vapor pressure). Value: decimal. Units: kPa-1.

### 7.4 BFolResp

Base Foliar Respiration Fraction - Foliar respiration as a fraction of maximum photosynthetic rate. Value:  $0.0 \leq \text{decimal} \leq 1.0$ . Units: proportion.

### 7.5 TORoot/TOWood

Turnover of Root/Wood - Fraction of root/wood biomass lost per year to damage, breakage or death. Value:  $0.0 \leq \text{decimal} \leq 1.0$ . Units: proportion per year.

## 7.6 Q10

Respiration  $Q_{10}$  value for foliar respiration, a measure of the rate of change of respiration when temperature is increased by 10 °C.

Value:  $0.0 \leq \text{decimal} \leq 10.0$ . Units: none.

## 7.7 FolLignin

Mass fraction of lignin in foliage tissue. Value:  $0.0 \leq \text{decimal} \leq 0.8$ .

Units: or gr/gr.

## 7.8 KWdLit

Annual decomposition rate of woody litter. Value:  $0.0 \leq \text{decimal} \leq 0.4$ . Units: percent per year.

## 7.9 InitialNSC

Amount of NSC assigned to newly established cohorts. Value:  $\text{integer} > 0$ . Units: g.

## 7.10MaxSLWFrac

DEF??. Value:  $\text{integer} > 0$ . Units: g.

## 7.11CFracBiomass

Carbon fraction of biomass by weight. Value:  $0.0 \leq \text{decimal} \leq 1.0$ .

Units: proportion.

## 7.12PreventEstablishment

Boolean variable turning establishment on or off. Value= “true” or “false”.

## 7.13FolAddResp

DEF??. Value:  $0.0 \leq \text{decimal} \leq 1.0$ . Units: proportion.

## 8 Input File – PnET Species Parameters

All parameters for a species appear on a single line. Parameters may appear in any order.

### 8.1 Example file:

PnETSpeciesParameters

SpeciesName	FolN	SLWmax	SLWDel	TOfol	AmaxA
AmaxB	HalfSat	H3	H4	PsnAgeRed	PsnTMin
PsnTOpt	k	WUEcnst	MaintResp	DNsc	
FracBelowG	EstMoist	EstRad	FracFol		
FrActWd					
abiebal	1.5	160	0	0.25	5.3
275	5	2	19	0.5	7
0.25	10	3	0.053	0.00002	
acerrub	2.5	65	0.2	1	-46
500	5	4	26	0.58	8
0.33	5	5	0.028	0.00004	
acersac	2.4	50	0.2	1	-46
275	5	2	23	0.58	6
0.33	10	1	0.02	0.00002	

### 8.2 SpeciesName

The species name as it appears in the species parameter input file (see Chapter 6 of the *LANDIS-II Model User Guide*).

### 8.3 FolN

Foliar nitrogen content (%). Value: 0<decimal <10. Units: %.

### 8.4 SLWmax

Maximum specific leaf weight at the top of canopy. Value: 0<decimal <1000. Units: g/m<sup>2</sup>.

### 8.5 SLWDel

Rate of change in specific leaf weight from the top of the canopy to the bottom. Set to zero to make SLW constant throughout canopy. Value: 0.0 ≤ decimal ≤ 2. Units: g<sup>-1</sup>fol.

## 8.6 Tofol

Turnover of Foliage - Fraction of foliage biomass lost per year. Typically the reciprocal of leaf longevity. Value:  $0.0 \leq \text{decimal} \leq 1.0$ . Units: proportion per year.

## 8.7 AmaxA

Intercept of relationship between foliar N and maximum net photosynthetic rate. Units:  $\text{nmol CO}_2 \text{ g}^{-1} \text{ leaf s}^{-1}$ . Value:  $-500 < \text{decimal} < +500$

## 8.8 AmaxB

Slope of relationship between foliar N and maximum net photosynthetic rate, such that  $A_{\text{max}} (\text{nmol CO}_2 \text{ g}^{-1} \text{ leaf s}^{-1}) = A_{\text{maxA}} + A_{\text{maxB}} * \text{FoliarN}$ . Units  $\% \text{N}^{-1}$ . Value: decimal  $> 0$ .

## 8.9 HalfSat

Half saturation light level for photosynthesis. Lower values reflect more shade tolerance. Value: integer  $> 0$ . Units: User choice. Typically  $\mu\text{mol/m}^2/\text{sec}$  or  $\text{W/m}^2$ . The units of PAR in the climate input file must be the same as HalfSat. **THE MODEL WILL NOT CHECK TO ENSURE THAT THE UNITS ARE THE SAME.** This is a user responsibility.

## 8.10 H2, H3, H4

Water stress parameters according to Feddes et al. (1978). See chapter 2.8. H1 is hardcoded at 0 meter pressure head. H2, H3 and H4 should all be positive values. Note that this is the absolute value of values usually reported in the literature.

## 8.11 PsnAgeRed

Reduction factor reducing leaf photosynthesis rate as cohorts age, with  $f_{\text{Rad}}=1.0$  at age 1 and  $f_{\text{Rad}}=0.0$  at the longevity specified in the LANDIS-II species parameter file. Longevity should be specified as longevity under optimal conditions because the various reduction factors will combine to almost always result in cohort death prior to the specified longevity age. A value  $< 1.0$  results in a rapid initial decline in max photosynthesis with age, a value of 1.0 results in a linear decline and a value  $> 1.0$  results in slow initial decline, according to  $y = (\text{age}/\text{longevity})^{\text{PsnAgeDecline}}$ . Cohorts die when NSC is  $< 1\%$  of the value of the other biomass pools

combined at the end of a calendar year. Value:  $0.0 < \text{decimal} < \infty$ . Units: proportion per year.

### 8.12PsnTMin

Minimum temperature for photosynthesis. Value: decimal  $\geq 0.0$ .  
Units: °C.

### 8.13PsnTOpt

Optimal temperature for photosynthesis. Value: decimal  $\geq 0.0$ .  
Units: °C.

### 8.14k

Canopy light attenuation constant (light extinction coefficient).  
Value:  $0.0 \leq \text{decimal} \leq 1.0$ . Units: none.

### 8.15WUECnst

Constant in equation for computing water use efficiency (WUE) as a function of VPD.  $\text{WUE} = \text{WUEConst} / \text{VPD}$ . Higher values result in higher WUE. Value: decimal  $> 0.0$ . Units: none.

### 8.16MaintResp

Loss of NSC due to maintenance respiration, depends on biomass according to  $\text{Loss} = \text{MaintResp} * \text{Biomass}$ . Value:  $0.0 \leq \text{decimal} \leq 1.0$ . Units: proportion of NSC lost per month.

### 8.17DNSC

Fraction of NSC relative to total non-foliar biomass that will be maintained as long as net photosynthesis exceeds maintenance respiration.

Value:  $0.0 \leq \text{decimal} \leq 1.0$ . Units: proportion of NSC.

### 8.18FracBelowG

Fraction of biomass that is belowground (root pool). Allocations vary at each time step to maintain this fraction. Value:  $0.0 \leq \text{decimal} \leq 1.0$ . Units: proportion.

### 8.19EstMoist

Tuning parameter to control the sensitivity of establishment (Pest) to soil moisture. Calculated using  $(\text{water}/\text{WHC})^{\text{EstMoist}}$ . High values make establishment more sensitive to moisture stress. A value of 1.0 results in a linear relationship between moisture stress and Pest, and little additional effect occurs with values over 50. Value:  $0.0 \leq$  decimal. Units: unitless.

### 8.20EstRad

Tuning parameter to control the sensitivity of establishment (Pest) to light level (radiation). Calculated using  $(\text{sub-canopy radiation}/(2 * \text{HalfSat}))^{\text{EstRad}}$ . High values make establishment more sensitive to radiation stress. A value of 1.0 results in a linear relationship between light availability and Pest, and little additional effect occurs with values over 50. Value:  $0.0 \leq$  decimal. Units: unitless.

### 8.21FracFol

Fraction of the amount of active woody biomass that is allocated to foliage per year. The active fraction of wood is calculated by the model using FracActWd. Value:  $0.0 \leq \text{decimal} \leq 1.0$ . Units: proportion per year.

### 8.22FracActWd

Shape parameter of negative exponential function that calculates the amount of woody biomass that has active xylem capable of supporting foliage. All wood is active when the parameter = 0.0, and increasing values decrease the fraction of active wood as biomass increases. Value:  $0.0 \leq \text{decimal} \leq 0.4$ . Units: unitless.

## 9 Input file - Ecoregion parameters

### 9.1 Ecoregion

The ecoregion name given must be defined in the ecoregion input file (see chapter 7 in the *LANDIS-II Model User Guide*). Ecoregions may appear in any order.

### 9.2 AET

Actual Evapotranspiration. AET is the actual amount of water delivered to the atmosphere by evaporation and transpiration. Parameter reflects aridity and is used to estimate leaf decay rates. Value: <0 integer <10,000. (Note: the value is typically <1000). Units: mm year<sup>-1</sup>.

### 9.3 SoilType

Abbreviation for the predominant soil type in the ecoregion. Soil type is used in the model to determine the water retention curve of the soil (see Figure 2 in section 2.8). The model currently supports SAND (sand), LOSA (loamy sand), SALO (sandy loam), LOAM (loam), SILO (silt loam), SNCL (silt clay loam), CLLO (clay loam), SACL (sandy clay loam), SICL (silt clay), CLAY (clay). These categories correspond with FAO soil types. Value: 4-letter string.

### 9.4 RootingDepth

Rooting depth, rooting depth in PnET-Succession is particularly important because it affects water storage capacity of the soil.

### 9.5 PrecLossFrac

Precipitation Loss Fraction. Proportion of precipitation that does not enter the soil (e.g., percolation, evaporation or runoff not due to soil saturation). Value:  $0.0 \leq \text{decimal} \leq 1.0$ . Units: proportion.

### 9.6 ClimateFileName

This parameter gives the name of the climate file for the ecoregion. The user may specify the same file for multiple ecoregions.

## 10 Output file - SiteData Table (Optional)

This comma-delimited table contains site-level PnET state variable values at the end of each month from the start of the spin-up period to the end of the simulation. The sites reported are specified in the input file. Values are for the entire cell and include the presence of all species and cohorts on the cell. Units for each variable are given in the header. This output is turned on in the PnET-Succession Input File by specifying the cell(s) to be output.

### 10.1 NrOfCohorts

Number of cohorts (all species) occurring on the cell.

### 10.2 MaxLayerStdev

Maximum standard deviation of biomass of all cohorts present on the cell. Used to calculate the number of canopy layers (section 2.4).

### 10.3 # of layers

Number of canopy layers on the cell.

### 10.4 Tday(C)

Mean air temperature (°C) in the daytime, derived from TMin and TMax from the climate file.

### 10.5 Precip(mm\_mo)

The monthly precipitation (as read from the climate file, mm/mo).

### 10.6 RunOff(mm\_mo)

Monthly runoff that occurs from precipitation when the soil is saturated (mm/mo).

### 10.7 Transpiration(mm\_mo)

Monthly transpiration (mm/mo).

### 10.8 PrecipLoss(mm\_mo)

Precipitation lost to evaporation, surface runoff and percolation as a function of the PrecipLossFrac parameter (mm/mo).

**10.9 Water(mm)**

Amount of soil water as calculated by the bulk hydrology model (mm).

**10.10 PressureHead(mm)**

Pressure head as calculated by the bulk hydrology model (mm).

**10.11 SnowPack (mm)**

Water equivalent contained in the snowpack (mm).

**10.12 LAI(m2)**

Leaf Area Index (all species combined)

**10.13 VPD(kPa)**

Mean vapor pressure deficit for the month (kPa).

**10.14 GrossPsn(gC/mo)**

Gross photosynthesis of all species combined (gC/mo).

**10.15 NetPsn(gC/mo)**

Net photosynthesis of all species combined (gC/mo).

**10.16 MaintenanceRespiration(gC/mo)**

Maintenance respiration of all species combined (gC/mo).

**10.17 Wood(gDW)**

Sum of aboveground woody biomass of all species (gDW).

**10.18 Root(gDW)**

Sum of root biomass of all species (gDW)

**10.19 Fol(gDW)**

Sum of foliage biomass of all species (gDW).

**10.20 NSC(gC)**

Sum of NSC (Non-structural carbon) of all species (gC).

**10.21 Litter(gDW)**

Biomass (all species) in the litter dead biomass pool (gDW/m<sup>2</sup>).

**10.22 CWD(gDW/m<sup>2</sup>)**

Biomass (all species) in the coarse woody debris dead biomass pool (gDW/m<sup>2</sup>).

## 11 Output file - CohortData Table (Optional)

This table contains monthly PnET cohort-level state variable values for the sites specified in the input file. A file is created when a cohort is established, and the records give month-end state variable values for the cohort from establishment to death (or the end of the simulation). Files are also produced for cohorts established during the spin-up period. Units for each variable are given in the header. This output is turned on in the PnET-Succession Input File by specifying the cell(s) to be output.

### 11.1 Age(yr)

Current age of the cohort (calendar years).

### 11.2 Dominance(-)

Relative dominance of the cohort in the canopy, scaled between 0 and 1, with 1 indicating no competing cohorts on the cell.

### 11.3 LAI(m2)

Leaf area index of the cohort.

### 11.4 GrossPsn(gC/m2/mo)

Cohort gross photosynthesis (gC/m2/mo).

### 11.5 FolResp(gC/m2/mo)

Cohort foliar respiration (gC/m2/mo).

### 11.6 MaintResp(gC/m2/mo)

Cohort maintenance respiration, including tissue repair and nutrient transport (gC/m2/mo). This amount comes out of the NSC pool.

### 11.7 NetPsn(gC/m2/mo)

Cohort net photosynthesis (gC/m2/mo).

### 11.8 ReleasedNSC (gC/m2/mo)

Amount of NSC released from the NSC pool and allocated to structural carbon pools (gC/mo).

**11.9 Folalloc(gC/m<sup>2</sup>/mo)**

Amount of carbon allocated to foliage (gC/m<sup>2</sup>/mo).

**11.10 RootAlloc(gC/m<sup>2</sup>/mo)**

Amount of carbon allocated to roots (gC/mo).

**11.11 WoodAlloc(gC/m<sup>2</sup>/mo)**

Amount of carbon allocated to aboveground wood (gC/mo).

**11.12 WUE(g/mm)**

Cohort mean water use efficiency (g/mm).

**11.13 Transpiration(mm/mo)**

Cohort water actually lost to transpiration (mm/mo).

**11.14 Fol(gDW/m<sup>2</sup>)**

Biomass of the cohort foliage pool (gDW/m<sup>2</sup>).

**11.15 Root(gDW/m<sup>2</sup>)**

Biomass of the cohort root pool (gDW/m<sup>2</sup>).

**11.16 Wood(gDW/m<sup>2</sup>)**

Biomass of the cohort wood pool (gDW/m<sup>2</sup>).

**11.17 NCS(gC/m<sup>2</sup>)**

Amount of carbon in the cohort non-structural carbon pool (gC/m<sup>2</sup>).

**11.18 NCSfrac(-)**

Fraction of carbon in the cohort non-structural carbon pool relative to the non-structural pools (wood, root and foliage). Cohorts die when NSCfrac is <0.01 at the end of a calendar year.

**11.19 fWater(-)**

Reduction factor related to water availability.

**11.20 fRad(-)**

Reduction factor related to light availability at the top of the canopy layer occupied by a cohort.

**11.21 fTemp\_psn(-)**

Reduction factor related to sub-optimal temperature for photosynthesis.

**11.22 fTemp\_resp(-)**

Reduction factor related to temperature effects on maintenance respiration.

**11.23 fAge(-)**

Reduction factor for age-related declines in photosynthesis efficiency.

**11.24 LeafOn(-)**

Indicates growing season status. When TRUE, new foliage can be added and old foliage has not yet been dropped.

**11.25 FActiveBiomass(gDW\_gDW)**

Fraction of active biomass. Indicates the computed fraction of wood biomass that is considered active and able to transport water to support foliage.

## 12 Output file – Site Estab Data Table (Optional)

This comma-delimited table reports site-level values related to species establishment at their levels at the end of each month. The sites reported are specified in the input file. Units for each variable are given in the header. This output is turned on in the PnET-Succession Input File by specifying the cell(s) to be output.

### 12.1 Water(mm)

Amount of water in the soil (mm).

### 12.2 SubCanopyPAR(-)

PAR (photosynthetically active radiation) reaching the ground. Units are user-defined in input files.

### 12.3 Pest\_speciesname

There is a column for each species containing the calculated probability of establishment as a function of the values of water and PAR.  $Pest = fRad^{EstRadSensitivity} * fWater^{EstMoistSensitivity}$ .

## 13 Appendix. Calibration tips.

1. First, set parameter values that are known from the literature (e.g., TOFol, FoIN, SLW, HalfSat, PsnTMin, PsnTOpt, k, etc.). HalfSat should be varied to reflect shade tolerance, because the LANDIS-II shade tolerance parameter has no effect in PnET-Succession. Some Pnet parameters (e.g., SLWDel, AmaxA, AmaxB, Q10, DVPD1, DVPD2) are hard to estimate and most studies use generic values (e.g., Aber et al 1995, Ollinger and Smith 2005).
2. Set parameters that will be held constant for your particular experiment or study (e.g., TORoot/wood, BaseFolResp, InitialNSC, MaxSlwFrac, etc.)
3. PsnTMin controls the length of the growing season. You should verify that the appropriate months are active (LeafOn=TRUE). PsnTMin should vary coarsely according to leaf-on and leaf senescence dates, and typically ranges from 1-5 °C for temperate species. PsnTMin will also control how productive the species is at the beginning and end of the growing season, and will produce a growth response to shifts in temperature even when the number of growing season months is unchanged.
4. In lieu of empirical values, PsnTOpt can be estimated using the average mid-summer temperature at the center of the species' range.
5. Calibration tuning is best done by matching simulated biomass increase to empirical biomass values for a species through time. Growth and yield tables are useful for this purpose and volume measures can be converted to biomass using specific gravity values for the species (Miles and Smith 2009). Ensure that units are the same as those output by PnET-Succession. Simulate a monoculture and plot Wood and Root+Wood (whole tree) biomass through time. There are some published estimates of whole tree biomass through time by species groups to provide some indication of belowground biomass (e.g., Smith et al 2006).
6. First, tune MaintResp by starting with a high value (e.g., 0.01) and reducing it to minimize the plateau effect (cap) on wood and root biomass growth. If MaintResp is too low, cohorts will fail to die when they are stressed or as they approach longevity. If MaintResp is too high the curve will abruptly plateau rather than gradually taper. It is recommended to use a common MaintResp value rather than tune biomass growth curves using MaintResp unless relative MaintResp values are empirically well-known. MaintResp is a primary driver of cohort mortality and species competitive interactions may not be reliable with different MaintResp values. Therefore, find a MaintResp value that works for all species.
7. The separation between plots of above ground biomass and total biomass (roots and wood) is controlled by FracBelowG. An increase in one pool will reduce the other pool.

8. Relative growth rate (among species) is controlled primarily with FolN. Conifers and deciduous species must be scaled separately when they use different values of AmaxA and AmaxB.
9. Relative growth rate is controlled secondarily with FracFol. Control the lag time of significant biomass increase (early years) using FracFol. For example, choose a benchmark (e.g., number of years to reach 5,000 g of wood biomass), and calibrate each species to vary this time according to relative growth rate expectations of the species. If the lag time is widely different among species, the species with long lag times will find it difficult to compete. It may be preferable to have similar lag times (e.g., ranging from 27 to 32 years) than to match empirical lag times closely; this may produce better competitive interactions in the model. Often empirical growth curves are measured in mixed forests, and shade-tolerant species will tend to have longer lag times than when grown in the open (e.g., eastern hemlock). It may be advisable to strive to keep FracFol similar among species, although experience has shown that evergreens and deciduous species may require quite different values.
10. The height of the biomass growth curve is primarily controlled by WUEc, although TORoot, TOWood and FrActWood have some effect. FrActWood has a somewhat unpredictable effect because although more active wood means more foliage in later years, it also increases maintenance costs. Remember that MaintResp can cause the curve to plateau regardless of other parameter settings. It is recommended to make major adjustments to the height of the biomass curve with WUEc and then make minor tweaks with FolN. It is recommended to keep TORoot/wood constant among species.
11. The timing of the peak of the biomass growth curve is primarily determined by species longevity and secondarily by PsnAgeRed.
12. NetPsn is primarily controlled by FracF and FracActWd, given FolN, SLW and BaseFolResp. Transpiration is highly correlated with Net Psn, scaled by WUE. Recall that GrossPsn is calculated by PnET-Succession using NetPsn and BaseFolResp, which is not intuitive.
13. LAI is controlled by SLW and FrActWood. LAI is a derived variable that basically divides foliage biomass by SLW. FrActWood (and SLW) have major effects on LAI and a modest effect on the biomass growth curve. It is recommended that you adjust LAI to within the empirical range after the growth curve is close to the desired shape. In lieu of empirical values, LAI should generally range between 2-4 for shade intolerant species and 4-6 for shade tolerant species.
14. Soil water is determined by inputs (precipitation) and outputs (PrecLossFrac, percolation out of the rooting zone (controlled by SoilType) and transpiration). Tuning of soil water is done primarily with PrecLossFrac and SoilType, which assumes that transpiration is correct if the photosynthesis and growth behavior is correct. H3 determines the order and relative dryness at which species start to experience water stress. H4 determines the order and relative dryness at which

species completely shut down because of water stress. The highest H4 value of all species on a cell determines how low soil water can be drawn down by transpiration. It is important to recall that pressure head is scaled logarithmically, so a gradient of relative H1-H4 values should not be specified using linear scaling.

15. dNSC has little effect on cohort competition unless it is set so low that the cohort has minimal reserves to survive stress, or so high that the species can rarely be stressed enough to die. Set this in the middle of the range of empirical measures of total % sugars and starch in active tissues.
16. InitialNSC similarly has little effect on cohort competition unless values among species vary by more than an order of magnitude.
17. EstMoistSens and EstRadSens. **Can Brian write this?**
